Aim: Both dose-escalated external beam radiotherapy (DE-EBRT) and androgen deprivation therapy (ADT) improve outcomes in patients with high-risk prostate cancer. However, there is little evidence specifically evaluating DE-EBRT for patients with high-risk prostate cancer receiving ADT, particularly for EBRT doses >74 Gy. We aimed to determine whether DE-EBRT >74 Gy improves outcomes for patients with high-risk prostate cancer receiving long-term ADT.

Patients and methods: Patients with high-risk prostate cancer were treated on an institutional protocol prescribing 3–6 months neoadjuvant ADT and DE-EBRT, followed by 2 years of adjuvant ADT. Between 2006 and 2012, EBRT doses were escalated from 74 Gy to 76 Gy and then to 78 Gy. We interrogated our electronic medical record to identify these patients and analyzed our results by comparing dose levels.

Results: In all, 479 patients were treated with a 68-month median follow-up. The 5-year biochemical disease-free survivals for the 74 Gy, 76 Gy, and 78 Gy groups were 87.8%, 86.9%, and 91.6%, respectively. The metastasis-free survivals were 95.5%, 94.5%, and 93.9%, respectively, and the prostate cancer-specific survivals were 100%, 94.4%, and 98.1%, respectively. Dose escalation had no impact on any outcome in either univariate or multivariate analysis.

Conclusion: There was no benefit of DE-EBRT >74 Gy in our cohort of high-risk prostate patients treated with long-term ADT. As dose escalation has higher risks of radiotherapy-induced toxicity, it may be feasible to omit dose escalation beyond 74 Gy in this group of patients. Randomized studies evaluating dose escalation for high-risk patients receiving ADT should be considered.

Keywords: radiotherapy, IMRT, dose, dose escalation, dose de-escalation, androgen deprivation therapy, prostate cancer

Introduction

Both dose-escalated external beam radiotherapy (DE-EBRT)¹ and androgen deprivation therapy (ADT) combined with radiotherapy² have been shown to improve prostate cancer outcomes based on meta-analyses of randomized trials. It is also thought that in the absence of ADT, EBRT doses >70 Gy provide a benefit,^{3–6} with several national guidelines recommending DE-EBRT up to 78–81 Gy for high-risk patients.^{7–9} These guidelines also recommend consideration of ADT with DE-EBRT. However, it has been noted that there is virtually no evidence for dose-escalating EBRT to these high dose levels in the setting of ADT.¹⁰

There are only two randomized trials of DE-EBRT for patients receiving ADT.^{11,12} Both compare 64 Gy EBRT with 74 Gy DE-EBRT. In these studies, all patients received

neoadjuvant ADT. Only one reported a significant benefit for dose escalation up to 74 Gy in the high-risk group.¹¹ The lack of data in general and the specific paucity for patients receiving >74 Gy has led some to question the benefit of DE-EBRT for patients receiving ADT.^{10,13}

Given the lack of available evidence, we evaluated whether dose escalation up to 78 Gy had any advantage in terms of prostate-specific antigen (PSA) disease-free, metastasis-free, or prostate cancer-specific survival (PCaSS) outcomes in our cohort of high-risk patients treated exclusively with long-term ADT and dose-escalated intensity-modulated radiotherapy (IMRT).

Patients and methods

Since 2006, the North Coast Cancer Institute has been implementing a dose-escalation program for patients with localized prostate cancer. The patients were initially treated with a dose of 73.8–74 Gy, which was escalated to 76 Gy in 2008 and then 78 Gy from 2009 until 2012. All patients were treated with either three-dimensional EBRT or IMRT, as has been previously reported.^{14,15} In brief, after institutional ethics approval (North Coast New South Wales Human Research Ethics Committee, reference number QA 101), the electronic medical record of our institution (Mosaik; Elekta, Crawley, UK) was interrogated to identify all patients with National Comprehensive Cancer Network-defined high-risk prostate cancer⁹ treated with our standard protocol of DE-EBRT and ADT. The exclusion criteria included patients post prostatectomy, had NCCN-defined low or high risk, were node positive, were metastatic, had histology other than adenocarcinoma, did not receive ADT, or were treated from 2013 onward. Patient consent was not required as this was a retrospective study

All patients were staged prior to treatment with computed tomography (CT) of the abdomen and pelvis and whole body nuclear medicine bone scan. The patients were prescribed ADT using leuprorelin or goserelin acetate monotherapy (using 3–4-month depots), with 3–6 months of neoadjuvant/concurrent ADT and 2 years of adjuvant ADT. The patients underwent transrectal ultrasound-guided insertion of fiducial markers followed by magnetic resonance imaging/CT fusion as previously reported,¹⁶ unless contraindicated. The patients were treated on our “Bowel and Bladder Protocol” involving low-residue diet, aperients, and a pretreatment oral fluid regimen to achieve a comfortably full bladder and empty rectum. The planning CT (2 mm slices) was performed with patients lying supine and immobilized with ankle stocks. The patients with seminal vesicle (SV) invasion (either clinically or on MRI) had the prostate and SVs included in the full-dose clinical target volume (CTV), treated to 73.8–78 Gy in

1.8–2.0 Gy fractions prescribed to the reference point. The patients without SV invasion had the prostate and proximal 4–8 mm SVs included in the full-dose CTV, and the distal SVs were included in a lower dose CTV (50 Gy, equivalently treated via an integrated boost). The CTV to planning target volume expansion was 5 mm. The patients were treated using a seven- to nine-field IMRT technique with the angles optimized to achieve target coverage and organ at risk sparing. Image guidance utilized either daily online kilovoltage portal images (matched to fiducial markers) or daily cone beam CT. The patients without fiducial markers (<1% of all patients) underwent daily cone beam CT matching to soft tissue and bone. The patients were followed up by the treating radiation oncologists, with data prospectively recorded in Mosaik. Biochemical failure was determined using the Phoenix definition (PSA nadir +2 ng/mL). All patients with biochemical failure were restaged with CT and bone scans, and more recently, prostate-specific membrane antigen positron emission tomography.¹⁷ Salvage ADT was initiated when the PSA reached 10–20 ng/mL or with documented metastatic disease.

Data were analyzed using SPSS v19 (IBM Corporation, Armonk, NY, USA). The 73.8 Gy and 74 Gy groups were combined into a single group designated as 74 Gy. Biochemical disease-free survival (bDFS; which we define as survival free of the event of PSA relapse of prostate cancer), metastasis-free survival (MFS; which we define as survival free of the event of metastatic relapse of prostate cancer), and PCaSS were calculated using Kaplan–Meier curves, and the log-rank (Mantel–Cox) test was used to compare survival between groups. The follow-up time was calculated from the date of commencement of ADT as recommended by Denham et al.¹⁸ Univariate analysis was done to assess the relationship between potential prognostic factors and bDFS, MFS, and PCaSS. The variables included were age (≤ 70 vs > 70), pretreatment PSA (< 10 ng/mL vs ≥ 10 ng/mL), Gleason score (6–7 vs 8–10), use of IMRT (no vs yes), and radiation dose (74 Gy, 76 Gy, and 78 Gy). The variables with a statistical significance < 0.25 were taken into account in a multivariate Cox regression analysis. All hazard ratios (HRs) were calculated with Cox proportional hazard models and expressed relative to the control group. *P*-values were two tailed and considered statistically significant if < 0.05 .

Results

In total, there were 479 high-risk patients treated with DE-EBRT and ADT, with a median follow-up of 68 months. Patient demographics are shown in Table 1. The 5-year

Table 1 Patient characteristics

Age, years

T1–2	299 (62.4)
T3–4	180 (37.6)

Abbreviations: IMRT, intensity-modulated radiotherapy; PSA, prostate-specific antigen.

bDFS for all 479 patients was 90.0%. The bDFS for 74 Gy, 76 Gy, and 78 Gy groups, respectively, were 87.8%, 86.9%, and 91.6% (Kaplan–Meier curves shown in Figure 1). These differences were not statistically significant ($P=0.8$).

The dose level had no significant effect on bDFS in either uni- or multivariate analysis. In multivariate analysis, factors predicting a higher hazard for biochemical failure included T3–4 disease (HR 2.0, 95% CI 1.2–3.5, $P=0.009$), PSA > 10 (HR 2.5, 95% CI 1.3–4.7, $P=0.006$), and Gleason scores 8–10 (HR 2.9, 95% CI 1.5–5.9, $P=0.003$). Further analyses grouping 74–76 Gy vs 78 Gy and 74 Gy vs 76–78 Gy also showed no effect on bDFS.

Figure 1 Biochemical disease-free survival for various dose levels.

Figure 2 Metastasis-free survival for various dose levels.

The 5-year MFS was 94.3%. The MFS for 74 Gy, 76 Gy, and 78 Gy groups, respectively, were 95.5%, 94.5%, and 93.9% (MFS Kaplan–Meier curves shown in Figure 2). The dose level had no impact on MFS ($P=0.8$). Factors predicting a higher hazard of metastatic failure in multivariate analysis included T3–4 (HR 2.1, 95% CI 1.0–3.8, $P=0.048$) and Gleason scores 8–10 (HR 2.9, 95% CI 1.2–7.1, $P=0.02$).

The 5-year PCaSS was 98.1%. The PCaSS for 74 Gy, 76 Gy, and 78 Gy groups, respectively, were 100%, 94.4%, and 98.1% (Kaplan–Meier curves shown in Figure 3). The dose level had no impact on MFS ($P=0.6$), and neither did any other factor.

Figure 3 Prostate cancer-specific survival for various dose levels.

Discussion

Dose escalation has been shown to improve bDFS for patients with localized prostate cancer;¹ however, ADT, particularly for high-risk disease, not only improves bDFS but also PCaSS and the overall survival.^{2,19} Not surprisingly, questions have been raised about the need for dose escalation in patients receiving ADT.^{10,13} There are two randomized trials that have investigated this dilemma.^{11,12} Creak et al, in a randomized Phase II trial, found a nonstatistically significant trend for PSA control favoring 74 Gy over 64 Gy. The reason for the nonsignificant result cannot be ascertained; perhaps, there was truly no difference between the groups or there were insufficient patient numbers. Regardless, Creak et al¹² did not analyze the results for high-risk patients. On the other hand, Dearnaley et al, in a randomized Phase III trial, found a significant progression-free survival benefit of DE-EBRT for 74 Gy (compared to 64 Gy). This finding was also significant for the high-risk subgroup.¹¹ However, this study is limited by the fact that EBRT doses were only escalated to 74 Gy and that patients only received short-course ADT (whereas long-term ADT has been found to be superior in some studies).²⁰

A few other studies evaluating dose escalation in the setting of ADT did not analyze results for high-risk patients and EBRT doses >74 Gy. For example, Denham et al²⁰ conducted a nonrandomized evaluation of EBRT dose levels up to 74 Gy and 46 Gy EBRT combined with high-dose rate brachytherapy. They found that higher doses did reduce local progression; however, there was no analysis of bDFS. In their study, there were 844 high-risk patients; however, the results were not analyzed for this group.

A study by Stoyanova et al¹³ evaluated the relative benefits of ADT and DE-EBRT up to 80 Gy; however, the results were not reported by the risk group. Despite this, the authors were able to conclude that the benefit of ADT far outweighed the benefit of dose escalation. This belief was echoed by Roach,¹⁰ who also attempted to address the relative benefits of dose escalation vs ADT via a literature review. With a paucity of high-quality studies, he concluded that the data supporting ADT were greater than the data for dose escalation. Indeed, in a previous series of patients with intermediate risk prostate cancer, we were unable to find any benefit of dose escalation in the setting of neoadjuvant ADT.²¹

In the present series, we report one of the largest cohort of patients with high-risk prostate cancer treated exclusively with a combination of long-term ADT and DE-EBRT. As far as we are aware, this is the only study evaluating the potential benefit of dose escalation beyond 74 Gy in the

setting of long-term (2–3 years) ADT and EBRT in the management of this risk group. We failed to demonstrate any statistically or clinically significant benefit for dose escalation up to 78 Gy.

Although dose escalation may have questionable benefits in terms of cancer outcomes, the adverse effects are well known. A meta-analysis of randomized trials of dose escalation with long-term follow-up showed that dose escalation increases both late genitourinary and gastrointestinal toxicities.¹ Even limited dose escalation from 74 Gy to 78 Gy in 2 Gy fractions has been shown to significantly increase toxicity.²² It is known that ADT has its own toxicities; however, many of these toxicities are potentially reversible.²³ Additionally, in some studies, ADT has been found to protect against both late radiotherapy-induced urinary and bowel toxicities,^{23,24} perhaps partly due to a reduction in prostate size reducing bladder and rectal dose.²⁵

If ADT is more beneficial than dose escalation, it may be possible to limit dose escalation to 74 Gy or possibly even reduce doses further (eg, to 70 Gy). Dose reduction has been possible in other cancer types where systemic therapy is given.^{26,27} It seems evident that further research should evaluate the relative benefits of high radiotherapy doses in the setting of long-term ADT for high-risk prostate cancer.

Our study has several limitations. We report a retrospective review, and thus, our findings should be regarded as hypothesis generating only. Although we have a reasonable median follow-up of 68 months, it is possible that any benefits of dose escalation might only occur with longer follow-up, as seen in the study of Dearnaley et al¹¹ of 74 Gy vs 64 Gy (having a 10-year median follow-up). Having said this, Dearnaley et al's biochemical progression-free survival curves started diverging at 2–3 years of follow-up and were separated by 5 years (indeed, nearly as separated as the curves at 10 years). We also do not report on doses >78 Gy, and it is possible that benefits may only be seen with much higher doses. We also note that prostate-specific membrane antigen positron emission tomography imaging was only available for the most recent follow-up period,¹⁷ and this may have unknown effects on our outcomes. Finally, we have not reported about toxicity, with the unknown interactions and relative quality of life between escalating doses and ADT requiring further study.

Conclusion

For the high-risk prostate cancer patients receiving neoadjuvant and adjuvant ADT, we found no benefit of increasing radiotherapy doses from 74 Gy up to 78 Gy. There is

little evidence overall for dose escalation in the setting of ADT, and it is apparent that further research (in the form of large-scale prospective randomized controlled studies) is required to investigate dose escalation, possible dose de-escalation, and the interaction of dose escalation and ADT in terms of toxicity and quality of life.
